ABSTRACT

This thesis develops a prototype multimedia database from which interface relationships and cost tradeoffs in the early stages of development of the Sea Launch and Recovery System (SEALAR) program can be rapidly and easily explored and evaluated. This prototype is developed employing HyperCard/Macintosh and demonstrates the feasibility of employing off-the-shelf technology to solve real world problems. The goal of attaining a cost effective system for access to space is thereby enhanced and brought one step closer to reality. Implementation issues are discussed and evaluated along with possible future enhancements to the model.

ACKNOWLEDGMENTS

I would like to thank my advisor, Professor Michael Melich, for his guidance and encouragement over the past few months. His creative ideas and enthusiasm were always available. The help of Professors Dan Boger and Donald Lacer have as well been invaluable to me. I have learned a great deal in working with both of them. I feel honored that they have taken the time to carefully read my thesis and provide many useful comments, helpful suggestions, sound advice and continued support throughout my studies.

I also wish to express my thanks to Ginny Scout for her careful editing, formatting and typing of this manuscript.

The greatest thanks go to my wife and family who have continually and enthusiastically encouraged me throughout this endeavor.

I. INTRODUCTION

In America, "No natural boundary seems to be set to the efforts of man; and in his eyes what is not yet done is only what he has not yet attempted to do."

Alexis de Tocqueville

A. PURPOSE

This thesis was produced with the objective of illustrating an innovative method for the tracking of interface relationships and cost tradeoffs in a mid-sized research and development program. The Sea Launch and Recovery System (SEALAR) was selected to be modeled because it is presently in the early stages of development and is the type of program which readily lends itself to be analyzed via a multimedia type database, in this case, Macintosh HyperCard®. The overall objective is to focus the reader's attention on the method of presentation and the flexibility and potential of the program employed.

The decision to use HyperCard, a trademark of Apple Computer Incorporated, was based upon several factors. Specifically, HyperCard's object-oriented properties support ease of development, portability and reusability of modules. These characteristics are enhanced by the ability of HyperCard to link to modules within itself or to other programs. These aspects of the program will be discussed later. In addition, these same object-oriented capabilities provide the developer with a rapid, interactive prototype environment that greatly enhances debugging and ultimately results in a program that has significantly increased robustness over that offered in other conventional programming environments.

HyperCard provides the developer with a significant degree of flexibility and power, and a rich set of development tools and options. When combined, these establish a degree

of compatibility and cognitive richness found in few other programming environments. The human factors engineering and human interface technology found within the Macintosh operating system have been extended into HyperCard. These features allow the developer to easily acquire, manipulate and import text, sound and graphics into HyperCard without data conversion.

To demonstrate the viability of a multimedia data base employed in such an application, the SEALAR X-3 rocket was selected. Due to limited time and resources, this initial implementation was aimed primarily toward the prototype's propulsion system. However, it must be noted that this program is not designed to demonstrate applicability of a specific function, rather its purpose is to validate the integration possibilities across the entire functional spectrum of the SEALAR program.

B. STRUCTURE

The thesis is organized into five sections. The first section is essentially a political statement and assessment of where we are, how we got here, what avenues we are likely to pursue as a nation with regard to space utilization and exploration in the future, and what are the primary motivations and drivers of this process.

The second section, background, contains a brief history of development of the water launch concept, including a summary of the Hydra and Sea Dragon projects completed in the early 60's, the ancestors of the SEALAR concept.

Within the third section, programming environment, a brief overview is presented of the employment of HyperCard and an explanation of the object-oriented programming environment. It also includes a discussion of programming language features and capabilities.

The fourth section, application, the application, explains how the program was built and how to manipulate the stack and its numerous features. Within it is an explanation of the programs required to be installed on the computer in order to run the program and detailed instructions of how to operate it.

Finally, the analysis and conclusion section gives an explanation of what the employment of HyperCard programming could offer a program like SEALAR in terms of the ability to track the interface relationships between components of both off-the-shelf and custom engineered components, and the unique ability to quickly and objectively compare specification and costing tradeoffs with minimal effort and reasonable reliability. Implementation issues are discussed and evaluated. Future enhancements to the program are also discussed.

C. HISTORICAL PERSPECTIVE

Man's inevitable quest for knowledge and adventure in the exploration and utilization of space cannot be satisfied solely by the use of machines and robots, as recently proposed by some scientists and members of Congress. This is not to say that robots cannot play important roles in helping define and shape the environments in which we will travel and live in the future, and in acting as sentinels carefully placed along the way in advance of manned missions. However, in order to make these dreams of today a reality tomorrow, we require a system offering reliable and cost effective access to space.

In historical perspective, machines have never been used solely for the exploration of the earth and its many environments. Whether the objective was the conquest of the outer reaches of the atmosphere or the vast depths beneath the surface of the world's oceans, machines might have gotten there first but men were never far behind. Machines lack the innate ability to comprehend the unknown, i.e., they can only inform us about physical

quantities that we already are aware of. Of course they can quantify and analyze these known parameters more accurately and efficiently than a human. Therein lies both their utility and primary limitation. The conquest of space must be made by manned vehicles in conjunction with unmanned space probes.

We humans have made great strides in our initial exploration of space: the Apollo program, landing the first man on the Lunar surface and returning him safely to the earth; the Soyuz program, having a man spend 237 continuous days in space; and the Voyager program, a pair of unmanned space probes which explored the outer planets of our solar system, to name only a few. However, when compared to the timeline of aviation, which in many respects, was a similar development process, we find that space exploration is indeed still very young. Aviation had its beginnings with the Wright brothers first flight at Kitty Hawk, North Carolina in 1904. In comparison the first terrestrial instrument or probe, Sputnik, was placed in orbit in October 1957 by the Soviet Union, 34 years ago. Employing some simple arithmetic we find that if we add this figure to aviation's birth date of 1904, the result is 1938. Clearly, aviation was undergoing rapid advances at this point, but was still very young, with many highly significant improvements to be made in the next 53 years to bring us to the present. Thus it can be said with some confidence that space exploration is still in its infancy.

There is, however, one singular difference between the development of aviation as an industry and space as an industry. The development of the aviation industry, to a great extent, was performed by individuals and companies and was financed substantially with funds derived from the private sector. Even given the increased military importance attributed to aviation in the post WW I era, the private sector was to be the motivating force

that was to keep aviation moving forward. The military, up until the beginning of WW II, had not begun a credible and substantial development program for the sole purpose of developing military aircraft.

The above occurred because of several reasons. One was the relatively low cost of initial development of the airplane. The Wright brothers spent relatively little capital and a substantial amount of time in constructing their first aircraft. Another was the excitement and thrill of breaking records, of being the fastest or having flown the highest. During the 20's and 30's, individuals seeking to make substantial contributions to an infant industry were eager and willing to risk resources, time and, in some cases, even their lives. These achievements were recognized by numerous awards and trophies on both sides of the Atlantic and were given with increasing regularity in the early to mid 20th century. Last, and perhaps the most important, was the fact that enterprising individuals and companies with foresight and vision recognized the potential for realizing a profit from an initial investment.

In contrast, the development of the space industry has been, to a great extent, left in the hands of governments. The two primary reasons for this include, one, the relatively rapid realization by the military establishments of the world of the tactical and strategic applications of space vehicles and hardware, and two, the substantial cost required to develop, build, and launch space vehicles and hence to support a viable space program. While these reasons seemed valid and consistent for several decades, the paradigm in the early 90's now has begun to change. The world community has now largely acknowledged by consensus the end of the Cold War between the two superpowers. The American public has voiced increasing demands upon the US government to significantly reduce deficit spending and to increase support and funding for domestic programs. In the case of the Soviet Union, its public demands the substantial reform of the bureaucratic form

of government, a reversal of the trend of deterioration of their already stagnant economy, and a move toward an open market system interacting freely with Europe and the West.

As a direct result of the above factors, the trend is toward a reduction of the governmental control and subsidization of the space industry within the United States and the Soviet Union. This ultimately means that once again the private sector must be encouraged to bear the burden and take the required risks if we are to continue to explore and develop our understanding of space. However, because of the tremendous cost involved, this cannot happen of its own accord. The governments, endorsed by bold and strong political leaders of the world, must support and nurture this fledgling industry, at least until it gains sufficient momentum and becomes a going enterprise, i.e., until it becomes profitable. In retrospect, had H. G. Wells fictional Baltimore Gun Club been a reality, and if its visionary members possessed the enormous capital required to develop and test a space vehicle, the world could have been vastly different today.

As the decade of the nineties begins and we look toward the 21st century several important trends become evident. One, economies around the world are being restructured, primarily as a result of failed ideologies and of excessive deficit spending, both factors ultimately resulting in recession and economic stagnation. These realities will presumably lead to an altered global power structure based upon economics rather than strictly military prowess and might. World leaders will increasingly be compelled to recognize that in conjunction with this power comes the burden of accountability. While U.S. leaders have to some degree had to deal with this factor in recent years, other world leaders will find this a new and often annoying challenge. As a direct result of technological advances in the field of communications and travel in the last twenty years, news events and advertising have developed an informed and educated public and constituency. World leaders will be

increasingly held accountable for their actions and decisions, many of which may well have long term effects upon our global environment, as well as short term impacts upon regional economies.

Another important trend of the 90's will involve space. Its exploration, exploitation, and conquest will ultimately become dominant factors in defining our future and will hold the keys to our destiny. The realities of this statement will become increasingly evident as the decade unfolds. The earth provides only limited and inequitably distributed resources upon and beneath its surface. Scientists and environmentalists now acknowledge the perceptible and increasingly evident deterioration in the quality of our air and water. This sequence of disturbing events is occurring primarily as a result of the increasingly rapid exploitation and utilization of these finite resources. In the not so distant future, the use of extraterrestrial sources of power and raw materials may be not only economically prudent and advantageous, but the ultimate survival of the human species might well come to depend upon it.

The rules and paradigms have changed with regard to advancing technology and space exploration. Where deficit spending was the norm in the late 70's and 80's, and where excessive funding was ultimately available when required and not an insurmountable problem, the systems designed and built to date largely reflect this fundamentally flawed policy. Now, largely because of economic necessity and the lack of strong public support, we are compelled to rethink and redesign our programs, systems and hardware and attempt to achieve previously established goals within this now constrained economic environment.

As we plan, develop and prepare to launch our third generation earth sensing platforms and space probes, it is very likely that they will be significantly different from their predecessors in several aspects: they will be the result of significantly more international cooperation and funding; they will reflect the economic conditions and realities within

which they were conceived; they will likely be smaller and lighter, and inasmuch as possible be multifunctional in their capabilities. Additionally, they will be placed into space by a new generation of cost effective launch vehicles.

With the question of cost ultimately driving the whole issue of how and with what vigor a space program is to be pursued, it becomes evident that the major factors that drive cost must be fully understood and optimized. This question is not new. During the last of the Apollo missions in the early 1970's, forward looking individuals and planners had recognized that fiscal constraints would increasingly affect the U.S. space program. In the following excerpt from a Navy Space Systems Activity report, the answer to the cost dilemma was as follows:

The existing launch systems are very expensive to operate because their hardware is completely expended during each single mission - the present cost per pound of payload delivered to low Earth orbit is on the order of \$800 to \$1000 (FY 73). Economic considerations demand, and the experience gained during the first fifteen years of space flight makes it possible, to develop a reusable Space Transportation System for a vigorous continuation of space exploration during the next decade and beyond.

The development of the reusable Space Transportation System signals the end of the initial "brute force" period. Space flight operations will become to a large degree routine, like those of intercontinental airlines. Payload delivery costs to low Earth orbit will be reduced by the Space Shuttle to about \$150 per pound initially, and later to about \$100 per pound. The tremendous impact of the new Space Transportation System on Ground Operations including Range Safety, Communication, Reentry, Recovery and Retrieval will also be significantly reduced.[Ref. 1]

While the motivation and intent of the Space Shuttle concept was undisputably in the right direction, several elements ultimately leading to the failure to reach its cost objectives should be discussed. The Space Shuttle from its conception was to be a man-rated system. This factor in and of itself required extraordinarily high reliability, one of the primary cost drivers of such a space system. Secondly, the employment of numerous leading edge technologies throughout the system, some of which were not even through the research and development stage at its conception, contributed great uncertainty and unforeseen

technological challenges, ultimately leading to a significantly higher than estimated final system cost. Lastly, the cost of direct support, turnaround and refurbishment, and bureaucratic support were not accurately estimated nor maintained within reasonable bounds. "The Space Shuttle system has ended up being extremely expensive to maintain and launch." [Ref. 2]

By the mid 1980s, when the bills began to arrive in Congress, inquiring minds wanted to know if there was a better, more cost efficient system. Specifically, the House Committee on Science, Space, and Technology, and the Senate Committee on Commerce, Science, and Transportation requested and funded an assessment of available space transportation technologies. The broad realization was clearly that:

... low-cost transportation is one of the keys to more efficient exploration and exploitation of outer space. If space transportation costs were much lower, government agencies and private firms with good ideas for using the space environment might be more willing to risk their investment capital. [Ref. 3]

One plausible option was a concept which had been around for many years, and was in fact originally proposed by German missile engineers at Peenemünde, toward the conclusion of World War II. They proposed enclosing a V-2 rocket in a large canister and launching it out of the water in a vertical position. Following the war, the U.S. Naval Missile Center at Point Mugu, California continued research in this area under the name "Project Hydra". The stated policy of such research was "to develop vertical floating launch technology, and to apply it to both long-range missiles and satellite boosters". When the project was canceled in 1965, "it was generally conceded that the feasibility of this type of launch has been proven". [Ref. 4]

Ultimately, in order to realistically fulfill mankind's needs and desires, a reliable cost effective system is required for placing materials and supplies into space. Only then will man be able to continue to explore the universe and to discover what is on the next planet or beyond the next star.

II. CONCEPT AND DEVELOPMENTAL HISTORY

The decade of the 60's was perhaps the most exciting for space exploration and development to date. The decade began with the American and Russian space programs attempting to outclass one another in the "space race." With the lead position in serious doubt, the recently elected Democratic President, John F. Kennedy, "instructed his Vice President, Lyndon B. Johnson, to work with National Aeronautics and Space Administration (NASA) and seek out ways by which the United States could overtake the Soviet Union and demonstrate a superior American technology in full view of every nation on Earth. The ambitious goal would need dedication to objectives which would demonstrate a clear cut lead for the United States. It was decided that only a manned landing on the surface of the Moon was sufficiently in advance of contemporary Soviet accomplishments to give the space agency a fighting chance of getting there before the Russians." [Ref. 5]

Consequently, on 25 May 1961, President Kennedy went before Congress and called for a massive new commitment to space exploration: "Now is the time to take longer strides - time for a great new American enterprise - time for this nation to take a clearly leading role in space achievement, which in many ways may hold the key to our future Earth. I believe that this nation should commit itself to achieving the goal, before this decade is out, of landing a man on the Moon and returning him safely to the Earth. No single space project in this period will be more impressive to mankind, or more important for the long range exploration of space; and none will be so difficult or expensive to accomplish." [Ref. 5]

During this period

NASA was rife with optimism. The Apollo program had been authorized, and the entire country was excited about space. It was felt that a manned space station, a manned lunar base, or a manned mission to Mars would follow hard on the heels of Apollo. It was recognized, however, that not all of these missions, perhaps none of them, could be achieved unless the cost of transportation from earth to low orbit could be drastically reduced."[Ref. 6]

It was during this decade that two unique concepts were to be partially developed, which some 35 years later would provide the basis and conceptual foundations for the SEALAR program.

During the early 60's a U.S. Navy research team at the Naval Missile Center, Point Mugu, California, proposed development of techniques for launching large solid-propellant rockets from the ocean. The project, headed by Lieutenant Commanders John E. Draim and Charles E. Stalzer, came to be known as "Project Hydra." The initial concept was to attack directly the deficiencies of land-based launch and support facilities. Throughout the life of the project, "approximately sixty successful launches of rocket simulators and actual rockets confirmed the feasibility of the basic launch method--floating the rocket vertically and exhausting gases directly into the water. Shapes ranging from 3 feet to 105 feet in length, and weights of 20 pounds to more than 10 tons, have been successfully launched in this manner."[Ref. 7] Most were constructed from surplus Department of Defense and NASA assets, requiring little modification and costing little or nothing to acquire. While most tests employed solid-propellant rockets, several storable liquid rockets were also launched successfully.

The floating-launch concept was deceptively simple. Bare, unencapsulated rockets were waterproofed and made buoyant (through design or the addition of external floats). As the rocket motor built up to full thrust, the floating rocket rose vertically from its wet pad. Once clear of the water, it was indistinguishable from any land-launched rocket. Surprisingly, tests showed that the added upward force of **buoyancy** actually resulted in a performance benefit over land-launched missiles.[Ref. 8]

Several important military advantages became readily apparent as the project progressed. The team found that any type of platform (i.e., ship, barge, submarine, etc.) was easily made capable of transporting and launching a rocket employing the Hydra, or vertical floating launch technique. Very large missiles could be handled with little more difficulty than was experienced with smaller ones. Finally, it was realized that an awesome concentration of firepower was possible, since any number of missiles could be launched simultaneously.

As the Hydra Project progressed, the research team at Point Mugu proposed an ambitious and extensive development plan. Since it was determined that operational and technical problems would depend upon the specific size and mission of the vehicle produced, the team grouped the proposed vehicles into four classes. Figure 1 is reproduced from the "Hydra Program Plan"[Ref. 9] and depicts the class distinctions envisioned. It also illustrates the progress completed in reaching the denoted milestones.

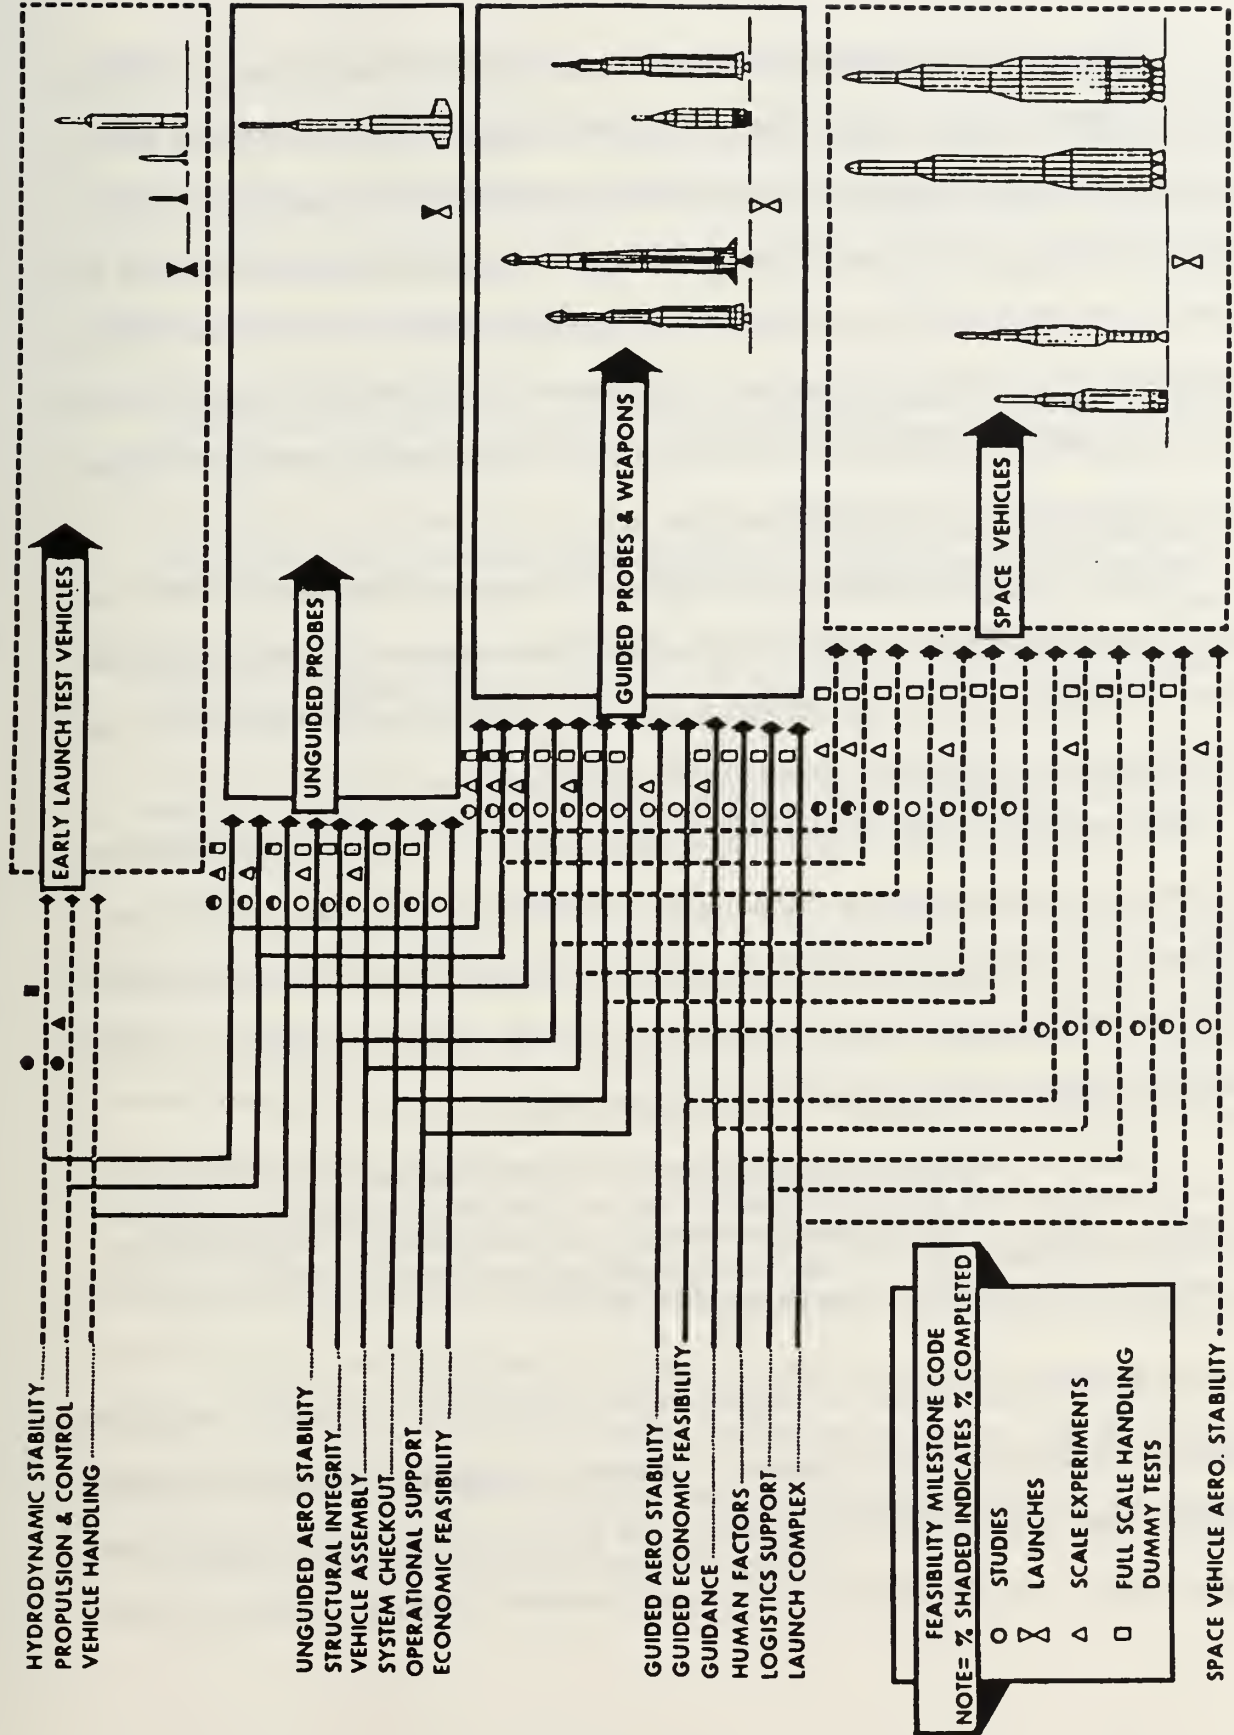

Figure 1

Within this figure is depicted a systematic approach to the development of a unique class of launch vehicles. Initially the prototype test vehicles, consisted largely of surplus and custom one of a kind rockets and missiles. The development of unguided suborbital probes followed, employing and refining the design features and elements derived from the previous test vehicles. They continued in complexity and development to the third class of suborbital guided probes and weapons. This process culminated into a class of orbital space vehicles, employing all of the features of the previous developmental stages and the same technology and construction principles.

Despite a very long string of successful launches and an ambitious program plan, the Navy canceled the Hydra program in 1965. While documentation explaining the decision is not available, one can only assume that with the Vietnam conflict looming on the horizon, the Navy had more important commitments elsewhere.

Also during this period, a retired Naval officer, Robert C. Truax, working as Director of Advanced Developments at the Aerojet-General Corporation, initiated an effort to discover the root causes of the high cost of space transportation and to formulate some principles for achieving more cost-effective designs. After collecting and examining all of the available data, his team reached the following conclusions:

Costs vary only slowly with size, but very sharply with complexity, reliability, design margins, and "programmed invention." A large fraction of the cost of a space launch resided in the propulsion hardware that was thrown away. A low-cost launch vehicle, therefore, should be big, simple, reusable, not too reliable, and use existing state of the art technology wherever possible.[Ref 10]

The Aerojet team went on to design a vehicle, which in their estimation, would be capable of fulfilling all foreseen mission requirements. Using accumulated data supplied from Marshall Space Flight Center (MSFC) and NASA, they devised a cost-optimized design based upon the principles previously described, making trade-offs largely

intuitively, and in general, tending away from existing configurations. This resulting design was dubbed "Sea Dragon." [Ref. 11] The economy of the "Sea Dragon" was obtained not through ever-increasing sophistication but through its great size, simplicity and reusability. [Ref 10] This prototype design embodied the characteristics deemed necessary for a low-cost launch vehicle:

- It was big, 500 feet tall and 75 feet in diameter, and had a liftoff weight of 40 million pounds; it was capable of lifting to low earth orbit (LEO) nearly 1.1 million pounds of payload per flight.
- It was simple; only two pressure-fed stages were used to attain LEO (300 nm). Each stage had only one main propulsion engine. Propellants used in the first stage were kerosene and liquid oxygen, in the second, liquid hydrogen and liquid oxygen.
- It was reusable; the simplest and lightest means available to return the stages to earth were used: a parachute-like drag device on the first stage, and a heat shield plus drag device on the second.
- It was sea launched; it was built in a drydock, towed to a lagoon, checked out dockside, fueled at sea, erected by flooding ballast, and launched directly out of the water. [Ref. 11]

The report was submitted to NASA for review and scrutinization. Eventually, being skeptical because of its significantly lower predicted cost per pound to low earth orbit, NASA let a contract to Space Technology Laboratory (now TRW) to reevaluate and presumably discredit the Aerojet team's costing analysis. Surprisingly however, the results of this costing review largely supported the original study's estimations.

Unfortunately, NASA funding began to decline after fiscal year 1964 and by the end of the decade was down from its peak of \$ 5,350.8 million to \$ 3,786 million in fiscal year 1970. This factor, combined with the public's apparent disinterest in repeated Moon landings by the early 70's and the increase in spending required to fight the war in Vietnam, led to the termination of funding for new vehicle concepts by NASA. As a result the "Sea Dragon" studies were never pursued and explored.

Looking back, one can only wonder what systems might be in place today had these two apparently promising concepts been allowed to be developed fully.

By the early 80's, numerous exercises, operational studies, and wargames had identified the requirements to proliferate and/or reconstitute space-based assets in times of crisis and in war. Most recently this need was demonstrated and validated in the Desert Shield and Desert Storm operations in the Middle East. This capability shortfall has led the Department of Defense to search for a low cost-per-pound to low earth orbit (LEO) space transportation system offering increased operational flexibility, redundancy, and responsiveness. Further, application of the concept could be realized within the commercial sector as a cost-competitive launch vehicle for industrial applications.

The motivation to pursue the sea launch and recovery concept is not new, as previously alluded to. Additionally, the requirements supporting the development of such a concept are not singular in nature. It is of fundamental importance to understand both the motivation and requirements for a sea launch and recovery type vehicle. Only then, can one fully appreciate the importance and significance of developing SEALAR as a viable alternative and supplement to the assets presently available for placing both men and equipment into space.

In 1986, DOD 5100.1 "Function of the Department of Defense and Its Major Components" described two functions of the Department of the Navy (DON):

- 1) Develop in coordination with the other services, procedures and equipment employed by the Navy and Marine Corps forces in the conduct of space operations
- 2) Provide sea-based launch and space support for the Department of Defense when directed

The Secretary of the Navy opened discussion within the Navy in 1987 asking such questions as: "Will the technology work?" "Is the SEALAR concept advantageous to the Navy?" "How promising is the development of a sea-based launch platform?"

Consequently, the SEALAR program was initiated after gaining support from the Chief of Naval Research, Commander Naval Space Command, and Director of the Naval Center for Space Technology (NCST). NCST of the Naval Research Laboratory (NRL) has become the primary source for personnel and resources for the project.

On the private sector side of the equation, Truax Engineering Inc. (TEI) submitted a proposal in response to the original NCST Broad Area Announcement which appeared in Commerce Business Daily on 25 August 1988. The proposal submitted included both analytical and experimental work which had been completed to date exclusively with private funds in support of the company's goal of ultimately demonstrating the principles set forth in the original "Sea Dragon" proposal some 35 years ago.

The Navy purchased the Truax Engineering prototype rocket, called the X-3, along with all associated ground support equipment for the fixed price of \$750,000. Along with the rocket the Navy gained any patent rights or other intangibles associated with it and owned by Truax Engineering Inc., including the right to have the equipment or any portion of it reproduced by others without further compensation.[Ref. 12]

The present SEALAR project is envisioned as the integration of the various design concepts which will ultimately lead to the development of a new family of simple, mobile and reusable space launch vehicles. These SEALAR launch vehicles portend to provide low cost and reliable access to space through the use of the following fundamental design concepts:

- Low cost liquid propellants (LOX, Kerosene, LH2)
Provides: Low cost, ease of handling
- Two stages to Low Earth Orbit (LEO) design
Provides: Simplicity, reliability and low cost
- Single engine per stage
Provides: Simplicity, reliability and low cost
- Pressure fed engine design
Provides: Simplicity, reliability and low cost

- Low chamber pressure engines
Provides: Simplicity, reliability and low cost
- Hydrogen dump cooling of large, low pressure thrust chambers
Provides: Low weight penalty allowing larger payloads
- Low cost high strength tanks, constructed employing conventional technology
Provides: Simplicity, reliability, performance, and low cost
- Global Positioning System (GPS) navigation
Provides: Simplified logistics, reliability and low cost [Ref 13]

Recently, Truax Engineering Inc., under the direction of the Naval Center for Space Technology and in conjunction with the Naval Research Laboratory have set up a comprehensive test plan. Initially, employing the X-3 rocket as the primary test vehicle, the test plan objectives include the verification of the design features of a water-launched vehicle, and multiple use and refurbishment characteristics. Also, through repeated launches and recoveries, experience can be provided from which more accurate estimates of turnaround costs may be made.

Lastly, and perhaps most importantly, the following two tables (Tables 1 and 2) vividly illustrate the advantages and benefits of the SEALAR concept over that of conventional expendable launch vehicles.

COMPARISON OF SEALAR AND EXPENDABLE LAUNCH VEHICLE (ELV) CONCEPTS

FACTORS UNIQUE TO SEA LAUNCH

TABLE 1

<u>Parameter</u>	<u>SEALAR Concept</u>	<u>Conventional ELVs</u>
Launch Inclination	Water Launch allows feasibility to match launch latitude to orbit inclination for optimization of payload performance	Fixed US launch site locations, at roughly 40N latitude, result in payload performance reduction for low-inclination orbits
Launch Rate	The Water Launch Concept allows for an unconstrained launch rate	Launch rate limited by pad availability (typically 4 launches/year/pad) - could preclude high launch rate programs
Launch Azimuth	Unconstrained with Water Launch affording maximum mission performance	Limited by ground overflight restrictions - required dog leg maneuvers reduce achievable performance and add complexity
Launch Pad Refurbishment	Water Launch results in minimal damage to launch support infrastructure, thereby reducing cost	Extensive pad refurbishment required after each launch

COMPARISON OF SEALAR AND EXPENDABLE LAUNCH VEHICLE (ELV) CONCEPTS

FACTORS NOT UNIQUE TO SEA LAUNCH

TABLE 2

<u>Parameter</u>	<u>SEALAR Concept</u>	<u>Conventional ELVs</u>
Launch Reliability	Ultra Conservative Design provides high confidence launch; may sacrifice some performance for reliability	Emphasis on high performance with inherently complex, pump-fed engines
Launch Vehicle Cost	Conservative approach of simplicity over optimized performance minimizes cost	Stress on high performance over simplicity results in high cost
Launch Vehicle Stage Reuse	Attractive cost savings possible through recoverable and reusable staging concept	Expendable Launch Vehicle concepts, by definition preclude reuse, a potential cost savings
Launch Support Infrastructure	Building-block launch vehicle approach provides for common mission support facility	Unique launch pads for each ELV type results in inefficient pad utilization and non standard logistic requirements

It appears that the development of the SEALAR technology will provide the U.S. Navy, as well as other government and commercial interests, a low-cost-per-pound space transportation system with increased responsiveness, survivability, capacity, flexibility, and operation availability. With such a space transportation system a reality, it will become possible to satisfy all of the present major space missions in an economic fashion, including Space Defense Initiative (SDI), the manned space station (Freedom), a manned Lunar base, and the Manned Mission to Mars.

III. THE PROGRAMMING ENVIRONMENT: HYPERCARD™

In this section the primary programming development tool, HyperCard/HyperTalk™, will be briefly described. The programming environment HyperCard was developed by Apple Computer® Incorporated. It is designed to run exclusively on the Macintosh™ family of computer hardware. It is now being marketed as an extension of the Macintosh operating system. The HyperCard, Version 2.0 edition, was used for the development of the program on which this thesis was based.

HyperCard is an event-driven, object-oriented programming environment that is driven by messages to and from objects. Actions are initiated in response to events which then send a chain reaction of messages from one object to another. HyperCard, also contains a general purpose programming language called HyperTalk. This programming language provides tools for painting, editing functions and semiautomatic program development. HyperCard is truly a multi-media development system that affords the programmer the ability to rapidly and easily integrate graphics, text and audio into an object-oriented environment.

The programmer interface with HyperCard is very intuitive and easily learned; this is true as well for the user. An individual with little or no programming background is able to create very professional looking programs without writing any code. At the other end of the spectrum, a experienced programmer is capable of creating powerful functions and commands written in other computer languages, which may not be presently available in the HyperTalk functions. HyperCard has proven to be a substantial labor saving developmental environment and has significantly extended the domain of software development.

HyperCard uses the metaphor of a stack as an object that can hold both processes and data, and exists only in the context of a stack. It is important to point out that a HyperCard stack is uniquely different from the classical data structure, in that it can be accessed from top or bottom or anywhere in between. HyperCard supports development of stacks that allow data, which may be any combination of text, graphics and sound, to be stored, linked, searched and or viewed. This unique set of attributes provides for the basis of the multi-media database application. Information may readily be linked relationally within a stack or from one stack to another. HyperCard is clearly not a replacement for traditional databases. However, as a stand alone multi-media database development tool, HyperCard allows applications to be constructed in minutes that would require monumental effort in conventional programming language.

Within the HyperCard programming environment there exist five pre-defined objects. They are buttons, fields, backgrounds, cards and stacks. All HyperCard objects are able to send and receive messages; have unique properties including script which is code associated with that particular object; and have a visible representation that may be turned on or off. A button is a specified area on a card that is accessible with the mouse pointer. Buttons may be graphical, textual, a combination of both or totally invisible. When the user clicks the mouse pointer on a button, a message will be sent to the button and the script of the button will be executed. A field is an area in which textual data is stored on a given card. Fields are not static. They may be adjusted to any desired size, shape or appearance. Field scripts, like all scripts in HyperCard, are also event driven. Backgrounds are objects that cards often times share to give the program a homogeneous look. Cards are the objects on which fields, buttons and backgrounds reside. A stack can

consist of only a few cards or several million depending upon the application. The stack, along with the objects it contains, cards, backgrounds, buttons and fields, and any attached outside resources, constitute the executable program.

Modularity is a unique property of objects in HyperCard. Once created an object may be moved in its entirety to another stack with its graphical appearance, scripts and resources intact. This feature makes HyperCard particularly suitable for rapid prototype development and facilitates code reusability.

Sending messages is an important characteristic of an object-oriented programming environment. HyperCard generates messages, called system messages, which are sent to objects in response to certain program events. This affords the programmer the ability to model real world data efficiently and accurately. It also permits the establishment of browse, search and reporting capabilities within a program.

Whenever script is executed a message is generated. The first object to receive the message is the sending object and if it has a message handler (a subroutine in HyperTalk) it will execute the handler. The script can also call the same message handler from which the message originated. This is called recursion in HyperTalk. HyperTalk is also capable of nesting, which would occur if handler 1 in object A calls handler 2 also residing in object A. These capabilities allow the developer to create data structures similar to those found in conventional programming languages.

Within HyperCard are found two types of objects: transparent and opaque. Transparent objects are virtually invisible, that is they allow the user to look down through layers of cards below the top layer. Opaque objects however are solid. Consequently, they block the user from observing objects directly below. Every HyperCard object is created in its own layer; the layers are placed one on top of the other as the objects get added to the stack. The layers perhaps can be best visualized as infinitely thin sheets of

clear plastic. Opaque objects are visible through all layers of the stack regardless of their relative stack position, that is unless they get covered by another opaque object in a subsequent layer which would render the lower object impossible to be seen by anyone looking down. Transparent objects allow the user to observe opaque objects below.

Buttons, which are a type of HyperCard object, can be layered into a stack like any other object. Whether transparent or opaque, buttons will react to pointer mouse clicks regardless of depth in the layer. This is different from transparency, in that, when an object's visibility is set to false the object not only cannot be seen but is also deactivated. However, attributes of an object whose visibility is set to false may be obtained or changed through the use of the scripting language HyperTalk. Visibility and layering together provide the programmer with the ability to construct complex data structures and establish inheritance of code by layering buttons on top of one another and passing discrete commands from one layer to another. This is a very significant attribute in that it greatly facilitates compactness and reusability of code. Specifically, the invisible button was essential for the development of the SEALAR program because it is by employing this feature that the user is able to define a pathway to a desired subsystem, component and piece or part. All that is required for the user is to click on a graphic representation and the program will respond by displaying a blowup of the selected graphic.

The two categories of layers found in HyperCard are background and card. Everything assigned to a background is active and visible on every card of that same background in the stack, that is anything placed into a background design gets copied onto every other card with the same background: this includes graphics, text, and buttons. The programmer can choose to place graphics, text, or buttons onto a specific card and have them visible only when that particular card is the top card in the stack, by placing those objects into the card domain. All objects in the card domain are in the very top layers of the

stack with background objects lying below. The card domain can be thought of as a foreground. Conceptually, it is very important to note that card objects are visible and active only in their respective layers, whereas background objects are visible and active for all cards sharing a particular background. In terms of creating applications, this subtle difference between foreground cards and backgrounds becomes an indispensable tool for the programmer to hide certain action buttons from the user at different points of the program by covering up an action button on a background card with an opaque object on a foreground card. Background buttons can be created only one at a time, each in its own layer; however, the user can not discern any difference between the two buttons or the two layers because both opaque buttons are readily visible and show no obvious indications of being in two completely different layers. Careful manipulation of the background and card layers enables the programmer to develop a look and feel which results in a user friendly interface. This also allows for the modeling of complex data structures that are analogous to everyday metaphors.

System protection for SEALAR is inherently important for the establishment of program and data integrity. This is easily supported by HyperCard in the form of its built in stack protection mechanism. Stack protection is provided by the system. The level of protection is determined by the programmer and is assigned via the "protect stack" menu which allows for the selection of virtually any level of protection desired. Passwords are available options that can be used to protect a particular stack. A more sophisticated level of protection exists by using the scripting language HyperTalk which allows the programmer to limit the data which may be accessed down to the data element level. This capability may be extended to password protection which can be applied to protect a

specific data element or specific function. By employing the scripting language HyperTalk a programmer has complete flexibility with regard to limiting users to specific functions and data elements.

Another extremely important aspect of HyperCard is its linking ability. HyperCard links are a method of establishing a unidirectional pathway from one card to another. Links may be between cards in the same or different stacks regardless of either card's relative stack position. Bi-directional links can also be programmed by inserting a unidirectional button on each card such that each card has a pathway to the other. To establish links between cards in the same stack either the unique card identification number is used as a destination address or the card name can be used. Links to cards in different stacks are exactly the same with the addition of the new stack name to the destination address. HyperCard linking enables the programmer to implement true conceptual relational database applications, that is, data never needs to be duplicated and there is no data redundancy. This is accomplished by HyperCard's ability to create links via unique identification numbers that are independent of data content.

HyperTalk is a general purpose programming language that contains an extensive set of commands and functions. It is also a special purpose language that tends to be better for some programming tasks than most other languages, such as construction of visual databases and educational systems. It is a very intuitive and natural language which tends to favor nonprogrammers in its grammatical style. The object-oriented nature of HyperTalk makes the scripting portion of the programs compact, extremely easy to debug and very portable from one to the other. The finished programs tend to be very intuitive for the user to operate and have a visual look and feel that in other languages would be hard to achieve. This makes HyperTalk a very labor saving programming language. One of the most powerful features of HyperTalk are the external commands (XCMD's) and external

functions (XFNC's) which allow virtual unlimited extendibility. When HyperTalk was created two interface capabilities were installed called XCMD and XFNC. These two items enable HyperTalk to search the resource fork of the stack for a command or function if it is not found with the stack script. This capability provides virtual unlimited extendibility to the HyperTalk language. HyperTalk will search the resource fork of the stack for an unknown command of the type XCMD and likewise will search for an unknown function of type XFNC for an unknown function. Therefore, when a programmer wishes to extend the language for HyperTalk, he can write a function or command in another language and move it into the resource of the stack where he wishes to use it. Consequently, extensions to the HyperTalk language are always carried with the individual stacks that require them. Selected commands and functions from a library of XCMD's and XFNC's are easily moved into and out of stacks as desired.

The HyperTalk scripting language is totally unique among programming languages. Command structures are English like sentences or phrases such as "go to card 8613" or "set the user level to 5." HyperTalk is also very forgiving in syntax and it allows multiple variations in command structure. This is a very important distinction in terms of ease of programming, project implementation and project modification.

Functions in HyperCard may be one of three types: HyperTalk defined, user defined, or XFNC. HyperTalk functions behave in the same fashion as conventional programming language functions. When a function is invoked in HyperTalk, the scripts are searched in a hierarchical fashion until a match is found. If it doesn't find a match then the resource fork is checked to determine if a XFNC is available. This method of determining function location allows the programmer to redefine system functions as well as define entirely new ones. The ability to redefine the environment proved very valuable as this program was built. While HyperTalk is powerful enough to handle most programming requirements, the

ability to write XCMD and XFNC in other languages is extremely useful. This capability allows discrete external functions and procedures to be executed from within a HyperCard stack.

There are two sound commands available in HyperTalk, play and beep. Play requires a digitized type resource to be available in the stack for the voice parameter. The play command is used to play digitized sound or to play music form a string of notes. Beep is used to invoke the system beep. Another common sound command which is an XCMD is called "Talk." Talk, uses another program called MacinTalk™, which is a product of Apple Computer Incorporated. It converts text or phonemes into computer generated speech. Both digitized speech and "Talk" were utilized throughout the SEALAR program in an effort to appeal to the user's audio sense and to promote a friendly "look and feel."

The most significant criticism of HyperCard is that its language HyperTalk is an interpretive language. In some applications this tends to degrade execution speed. This is offset, however, by HyperCard's rapid search and card selection rate. Another limitation is that, at present, HyperCard can only display one card on a black and white screen at a time. Some of these limitations have been remedied by the creation of handlers by individual programmers in the form of XFNC's and XCMD's and are available in the public domain. Presumably, future upgrades will be made available that will move HyperCard into the realm of color graphics and multi dimensional displays. These features will serve to make the challenges and options available to the programmer even more fascinating and interesting.

IV. APPLICATION AND IMPLEMENTATION

As designed and implemented the SEALAR prototype is based upon a single graphical stack which allows the user to readily visualize images of the rocket system, subsystem, or component. The HyperCard program provides the user with a visible graphic interface, supplemented with audio descriptions, and coupled with a technical textual description thereby reducing the technical knowledge required to become proficient in using the program.

The stack is constructed using modular design features. This aspect is of critical importance because it enables the software program to be dynamic and respond to frequent or periodic updates and revisions. By maintaining this modularity, changes can be implemented within one module with no adverse side effects to other modules within the program.

The SEALAR prototype is entered at the subsystem level. The user is then asked to select one of seven modeled subsystems available for examination. This approach is in no way intended to be all inclusive or static, rather it is intended to represent a reasonable subsystem break down of the X-3 rocket modeled. Appendix A depicts the stack developed for the SEALAR prototype program. Conceptually, there would be seven virtual stacks, with one representing each subsystem. Within each subsystem's virtual stack there would reside the actual individual component stacks. Quite literally, each component installed on the modeled rocket would have its own stack consisting of the myriad of subcomponents that make up the functional unit. This serves to demonstrate the modularity feature referred to earlier. As design changes and modifications are contemplated or implemented, only the corresponding stacks need be **updated, not the** entire program.

The SEALAR prototype represents a multi-media database. Graphics are employed to represent objects that were historically represented by textual descriptors or attributes. In this program the textual information is used to enhance and expand the meaning of the object the user is currently viewing. Audio is additionally employed to enhance the intuitive environment. When viewed on the whole, the program provides a true multi-media presentation.

The background buttons which appear on every card of the stack are an integral part of the look and feel of the SEALAR prototype. Examples of these background buttons include HELP, LIBRARY, SEARCH, etc. The HELP button allows the user to quickly refer to a system reference manual if disoriented while navigating through any portion of the system. The TECHMAN button gives the user instant access to the pertinent section of the "X-3 Technical Manual"[Ref. 13], that applies to the particular subsystem or component currently being viewed. A copy of this technical manual is included as Appendix C. The "Previous Card" button located in the upper right hand corner of every card enables the user to return to the previous card viewed and in this manner literally to back out of the graphical path just navigated. The rocket button located in the upper left hand corner of every card provides the user with the ability to immediately return to the beginning of the graphical hierarchy of the subsystem stack so that multiple subsystems or components can be investigated without having to exit and reenter the program.

All graphic buttons are invisible so that they can be positioned over the various graphics found on each card. Special buttons are also utilized throughout this program. For example, the COST button instructs the HyperCard program to open a spreadsheet application in another program. In the case of the SEALAR prototype, the spreadsheet program employed was Microsoft® Excel, version 3.0. This program exhibited the capabilities to perform and display the required continuous costing computations and the

tracking of the changing interface relationships in an efficient and flexible manner. These features are demonstrated in the cost analysis of the propulsion subsystem included as Appendix D. It is in this manner that the component and subsystem costs and interface relationships can be tracked, evaluated and maintained.

The HELP stack is an integral part of the entire program. It has been developed to provide the user with an intuitive look and feel that will answer any program specific questions that may arise at any level within the SEALAR prototype program. Help has a search function that eliminates the need to page through the entire stack to answer a single question and it fully defines the functionality of all background buttons. In addition to the functionalities described above, several scripts were employed to automate the development process. This capability significantly enhanced the development process and helped make the SEALAR prototype a reality.

The graphics in the stack were scanned into a Macintosh II[®] computer using a Hewlett Packard Scan Jet[®] scanner from reduced sized blue prints. The scanning program used was called Deskscan[®] version 1.0, developed by Zedcor Inc. The graphics were then imported and enhanced in a program called Deskpaint[®] version 1.05, also by Zedcor. They then were copied and pasted into Superpaint, a graphics program developed by Silicon Beach Software Inc. From this Superpaint file each graphic was brought into the HyperCard program and placed onto an individual card. These cards then comprise the SEALAR prototype stack.

The SEALAR program can be run on any Macintosh Plus with 4 megabytes RAM internal and a 20 megabyte harddrive. The installed programs required on the computer include Macintalk, HyperCard version 2.0 and Microsoft Excel version 2.1. The final file sizes for the program were as follows: the HyperCard file was 433K, and the Microsoft Excel file was 17K.

V. ANALYSIS AND CONCLUSIONS

This study indicates that it is indeed possible to develop a reliable and accurate system for the tracking of costs and interface relationships through the employment of off the shelf multimedia technology. This approach offers several advantages over those conventionally employed. Development time using this type of technology is dramatically reduced due primarily to its object-oriented nature, overall system environment, and extensive set of development tools available. The testing of the working prototype can be carried out throughout the development process to verify accuracy and program operation. Software and hardware acquisition and maintenance are both relatively inexpensive and easily attainable because of the use of off-the-shelf equipment and programs available commercially. The level of friendliness of the program greatly facilitates the acceptance by initial users, and the lack of a formal or complex query language significantly reduces training time. Lastly, because of the modular construction of the program, changes and revisions to individual elements are easily made and do not affect other modules within the program.

Having the basic computer program completed, it will now be relatively simple for the continuation of development into the next rocket to be constructed. The most critical aspect of this development will be the acquisition of accurate and detailed costing and parts data from the contractors involved. Additionally, the development of a method to accurately track manhours for construction, design and development and those costs associated with these areas will be required. The tracking and optimization of cost and interface interactions will be critical to the SEALAR program's success. In conclusion, it has become evident that this can be accomplished both accurately and economically through the

employment of multi-media technology. This approach will contribute significantly to SEALAR's viability among the launch vehicles both in the inventory today as well as those on the drawing boards for tomorrow.

As of the date of completion of this document, the SEALAR program remains in the proof of concept phase. Initial plans for a July 1991 launch of the proof of concept vehicle, the X-3 had to be scrubbed after an oxygen leak developed in the pressurized oxygen tank during a static test. Subsequently it was determined that all of the X-3's tanks needed to be replaced. Plans now include the building of the X-3D, the follow-on rocket, and in its construction employ stainless steel tanks vice the maraging steel of those used in the X-3.

APPENDIX C

X3 VEHICLE DESCRIPTION

The X3 rocket vehicle has been designed primarily to serve as a test vehicle to demonstrate the water launch and recovery of reusable pressure fed liquid fueled rockets. The X3 rocket is a relatively simple stored gas pressure fed liquid fueled propulsion design (Huzel and Huang, 1971). Pressure fed designs are generally simpler and more reliable than turbopump designs as the turbopump itself is generally quite complex. On the other hand, in pressure fed designs, the fuel and oxidizer tanks must be stronger to withstand the ullage pressure. Correspondingly these tanks are thicker and heavier. The stronger tanks provide some synergistic advantages in simplifying the recovery process and generally making the rocket less susceptible to handling damage.

X3 vehicle specification:

Height	276 in
Diameter	25 in
Launch weight	3000 lb
Burnout weight	1000 lb
Engine thrust	4000 lb
Engine type	4 Rocketdyne LR-101
Burn time	114 sec
Fuel	Kerosene
Oxidizer	Liquid oxygen
Fuel and LOX feed	Helium pressurization
Fuel and LOX tank material	Vasco 250 maraging steel
Guidance	Strapdown inertial

Structure:

Fuel and oxidizer tank weights are a significant issue in a pressure fed rocket. Composite materials, cryostretched steel and maraging steel are prime candidates for the

tanks in terms of strength to weight ratios although relatively little is known about the associated cryogenic properties. Composite materials have provided the highest strength to weight ratios to date although cryogenic characteristics are virtually unknown. Further investigation of both composite materials and cryostretched steel tankage is planned in other phases of the SEALAR program.

Maraging steel, as used for both the X3 vehicle fuel and oxidizer tanks, provides an excellent strength to weight ratio. In addition to containing the pressurized fuel and oxidizer, the tanks also serve as the primary vehicle structure. The tanks have held up well in a series of helicopter drop reentry simulation tests. Some stress corrosion has been observed in test samples.

The X3 rocket fuel is kerosene. The oxidizer is liquid oxygen (LOX). This combination is both relatively low cost and easy to handle. The RP-1 fuel and LOX tanks form the basic rocket structure. Both tanks are pressurized to 600 psi by gaseous helium supplied from a titanium pressure vessel. The pressurized RP-1 kerosene is also used as a hydraulic fluid for the thrust vector control (TVC) system.

Propulsion subsystem:

Helium is stored in a high pressure titanium sphere in a chilled gaseous form providing a 5-to-1 tankage weight saving over the equivalent ambient temperature storage. The X3 helium tank contains 29.8 pounds of helium at 160° R which is pressurized to 3250 psi from ground service prior to launch. The helium tank outlet is connected to a series of heat exchangers. A much higher ullage mass utilization can be achieved by preheating the helium. Additionally, downstream pneumatic components need not withstand cryogenic temperatures. The heat is exchanged with the kerosene fuel flowing to the engines. The heat exchanger outlet is connected to a helium pressure regulator which regulates the helium

pressure to 600 psi. The helium regulator used in the X3 vehicle was originally developed for use as part of the Agena spacecraft attitude control system. A relief valve located on the regulator protects the vehicle from overpressure in case of a regulator failure. The regulator outputs are passed through pressurize/vent valves to the kerosene and LOX tanks. To further minimize the helium tank size and weight, the rocket is initially pressurized from a ground-based helium supply.

The fuel tank, containing 685 pounds (100 gallons) of RP-1 kerosene jet fuel, is pressurized to 600 psi by the vehicle helium subsystem. The fuel tank is manufactured out of 0.060 inch thick Vasco 250 maraging steel to provide a high strength to weight ratio. A capacitive sensor within the tank provides a measure of the fuel load within the tank. The LOX tank is located aft of the fuel tank to minimize the length of the cryogenic LOX plumbing. The rearward LOX tank position however somewhat reduces the vehicle dynamic stability. The RP-1 tank outlet is connected to the engines through a pneumatically operated Emergency Fuel Valve (EFV) and the helium heat exchanger. The pressurized RP-1 is also used to operate the thrust vector control servovalves.

The LOX tank, containing 1294 pounds (140 gallons) of liquid oxygen, is pressurized to 600 psi by helium in a manner similar to the fuel tank. The LOX tank is manufactured from 0.060 inch thick Vasco 250 maraging steel which provides the required strength to weight ratio. A capacitive sensor within the tank provides a measure of the LOX load within the tank. The LOX tank outlet is connected to a Propellant Control Valve (PCV). The PCV modulates the LOX flow rate in order to insure a simultaneous fuel and LOX burnout. The PCV position is controlled from a signal generated by the relative difference between the fuel and LOX tank level sensors.

Both the fuel and LOX tanks feed a cluster of four Rocketdyne LR-101 engines providing a total of 4000 pounds of sea level thrust. The LR-101 engines were originally

used for vernier steering of the Atlas, Delta and Thor launch vehicles. In the X3 vehicle, each engine is pivoted along one axis. The cluster of 4 gimbaled engines provide complete yaw, pitch and roll control. The engines are operated at a relatively low chamber pressure of 360 psi.

Engines:

The Rocketdyne LR-101 engines are regeneratively cooled by passing the fuel through the nozzle and throat regions prior to thrust chamber injection.

Rocketdyne LR-101 rocket engine specifications (single chamber):

Propellants:

Oxidizer.....	Liquid Oxygen (LOX)
Fuel	RP-1 (Kerosene)

Thrust chamber physical characteristics:

Combustion chamber

Diameter	2.73 in
Volume	41.76 in ³
Area	5.86 in ²
Characteristic length.....	20.00 in
Contraction 1/2 angle	15 degrees
Expansion 1/2 angle.....	15 degrees

Nozzle:

Throat diameter	1.63 in
Exit diameter	3.87 in
Expansion ratio	5.622 :1
Throat area	2.088 in ²
Exit area	11.74 in ²
Weight (approx)	12.0 lb

Steady state performance:

Thrust (sea level)	1007.5 lbf
Thrust (vacuum)	1180.4 lbf
Specific impulse (Isp)	205.4 sec ⁻¹
Chamber pressure	360.0 psi
Mixture ratio	1.9:1
Fuel flow rate	1.692 lb/sec
Oxidizer flow rate	3.214 lb/sec
Characteristic velocity (C*)	4930. ft/sec
Thrust coefficient	1.340 (sea level)
Thrust coefficient	1.570 (vacuum)
Injector pressure drop	275. psid

The LR-101 engines are started by pressurizing the fuel and LOX tanks, firing an igniter in each engine, verifying correct igniter operation and opening the EFV and LOX valves.

The engines are ignited by a set of pyrotechnic igniters inserted into each engine throat. Each igniter is a single shot device using a solid propellant charge of hydroxyl-terminated polybutadiene, ammonium perchlorate plus magnesium. The charge is ignited using a standard Atlas electric match coupled through a BKNO₃ tablet. The entire charge is contained within the phenolic tube. The flame exits through opposing vents directly into the thrust chamber. The igniter is held in the thrust chamber by an aluminum spider bracket.

Correct igniter operation is verified by a thermocouple attached to each igniter. It is imperative that all igniters are burning prior to the start of fuel and LOX flow or a hard start may result. A hard start is an explosion internal to an engine caused by an external flame

source propagating rearward into the engine. A hard start may result in a substantial overpressure which can permanently damage the engine. The igniter is ejected approximately 1/2 second after the engine start when the aluminum spider melts.

After engine burnout, the propellant valve is closed to retain helium pressure to enhance the fuel and LOX tank strength during reentry. Engine burnout is identified by monitoring the thrust chamber pressure. Burnout is at 180 psi corresponding to 50% of nominal chamber pressure. Residual pressure in the tanks strengthens them during water impact. After landing, the tanks are vented (made safe) either by an RF command or manually.

The smaller propulsion system valves are directly controlled by electrical solenoids. The larger valves such as the EFV and LOX valves are operated by helium pneumatic pressure using small solenoid pilot valves for control. Pressure transducers are installed on the helium, fuel and LOX tanks. An additional pressure transducer is installed on one engine to monitor chamber pressure during flight.

During the static test firing phase, additional transducers are included. Examples of additional transducers include fuel and LOX flow rates, chamber pressures for all engines and helium heat exchanger temperatures.

Thrust vector control:

The rocket steering is controlled by a Thrust Vector Controller (TVC). Each of the four LR-101 rocket engines can be swiveled on one axis by a hydraulic actuator. The engine swivel range is 10 degrees, providing a maximum two-engine lateral control thrust of 350 pounds. When opposite engine pairs are moved together, yaw or pitch control are obtained. Roll control is obtained by moving opposite pairs differentially. The command signals to the TVC originate in the Flight Control Computer (FCC).

The actuators are controlled by Moog proportional servo valves. The pressurized fluid for the hydraulic actuators is RP-1 rocket fuel supplied directly from the fuel tank at 575 psi. No boost pumps are used. The servo valve output is dumped overboard. The actuator position is sensed by a Linear Voltage Differential Transformer (LVDT) and signal conditioner assembly providing a voltage proportional to engine gimbal angle. The LVDT is rugged and well protected from saltwater effects.

A servo controller compares the FCC commands with the LVDT sensed actuator positions. The error signal is used to control the servo valve so as to null the position error. The small signal bandwidth is 18 Hz because of the low hydraulic pressure, the system becomes slew rate limited (130/sec) with a 4.5 Hz large signal bandwidth (Witham, 1990).

The maximum yaw and pitch thrust is limited to approximately 350 pounds by a 10 degree gimbal angle. The lateral thrust is converted into a moment as a function of distance between the engines and the time varying center of gravity location. If the vehicle reaches a sufficiently high angle of attack (α) at a high dynamic pressure (q), an insufficient control authority may allow the rocket to become unstable. Typically, the most critical flight regime is in the peak dynamic pressure (max q) region, near 30,000 ft. In this region, the angle of attack is limited to approximately 5 degrees. Substantial wind shears induced by jet streams are common at this altitude. Because of an unacceptable control authority, small fins have been added near the tail to shift the center of pressure rearward.

Recovery system:

The X3 rocket is recovered after use by a pair of parachutes. At 10,000 feet, a drogue parachute is deployed by a drogue gun controlled by the FCC. The drogue parachute is an

8 foot diameter Kevlar hemi-flo design manufactured by Paranetics. This Kevlar drogue parachute was initially designed for a different version of the X3 rocket which required a very high altitude drogue parachute deployment.

In this version of the X3, the drogue parachute is used to provide the initial deceleration, extract the main chute and for propellant settling in certain abort situations.

During an abort, the drogue parachute is deployed to slow the rocket. The fuel and LOX settling is dumped through the engine. In order to prevent the LOX is dumped overboard first. Later, the fuel is dumped overboard.

The main parachute is deployed at 1000 feet. The chute is used to extract the main chute from a container. The chute is disreefed to a diameter of 46 feet. The rocket enters the water tail first at 32 feet per second. The fuel and LOX tanks are pressurized at water entry to provide additional strength.

After landing, a radio beacon, dye marker and flashing light assist in locating the vehicle.

X3 vehicle weight summary (10/10/90):

Primary tank structure.....	344.0
Fuel tank	
Center section structure	
Helium tank	
LOX tank	
Instrument bulkhead	
Oxygen subsystem	
Pressure vent valve.....	1.25
Tank level sensor probe.....	3.5
Plumbing, wiring, misc.....	3.25
